ORIGINAL ARTICLE

Achilles enthesitis defined by ultrasound is not associated with clinical enthesitis in patients with psoriatic arthritis

Brigitte Michelsen,1,2 Andreas P Diamantopoulos,1 Dag Magnar Soldal,1 Hilde Berner Hammer,3 Arthur Kavanaugh,4 Glenn Haugeberg1,2,5

ABSTRACT

Objective To compare clinical and ultrasonographic (US) evaluation of Achilles enthesitis in patients with psoriatic arthritis (PsA).

Methods The Achilles insertion of outpatients with PsA was examined by clinical assessment of tenderness and US evaluation of (1) inflammatory activity (defined as the presence of power Doppler signal, tendon thickening and/or hypoechogenicity) and (2) structural damage (defined as the presence of erosions, calcifications and/or enthesophytes). Univariate and multivariate logistic regression analyses were performed to explore the associations between clinical characteristics and US scores.

Results 282 Achilles tendons in 141 patients with PsA were assessed. Mean (SD) age was 52.4 (10.2) years, disease duration 9.5 (6.6) years and 50.4% were females. Palpatory tenderness was found in 88 (31.2%), US-verified inflammatory activity in 46 (16.3%) and structural damage in 148 (52.5%) of the Achilles. Total US scores, as well as their components, were similar for patients with and without palpatory tenderness. None of the clinical characteristics were associated with US scores.

Conclusion There appears to be a lack of association between clinical and US signs of Achilles enthesitis in PsA. Age, BMI, regular physical exercise and current use of biological disease-modifying antirheumatic drugs were associated with structural damage on US.

INTRODUCTION

Evaluation of inflammation and structural integrity of periarticular structures such as entheses can be challenging. This is even the case for large, accessible entheses such as the Achilles tendon insertions. It has been suggested that enthesitis may be both overestimated and underestimated by clinical examination in psoriatic arthritis (PsA).1-4 Ultrasoundography (US) is a sensitive tool for the assessment of musculoskeletal inflammation, including enthesitis, and is increasingly used in clinical practice, where it may be considered as an extension of the clinical examination.5

We have previously reported significant discrepancies between US and clinical findings in PsA.6

In the present study, we aimed to compare the clinical and US evaluation of Achilles enthesitis, an enthesis site frequently affected in patients with PsA. Further, we aimed to explore the associations between US-verified Achilles enthesitis and clinical characteristics.

Key messages

What is already known about this subject?

► Recent studies have indicated the benefit of ultrasonography (US) evaluation in addition to clinical evaluation in psoriatic arthritis (PsA).

What does this study add?

► Our findings underline the discordance between clinical and US evaluation of Achilles enthesitis in PsA. None of the clinical characteristics were associated with inflammatory activity at the Achilles, whereas structural damage was associated with age, body mass index, regular physical exercise and current use of biological disease-modifying antirheumatic drugs.

How might this impaveous studies ct on clinical practice?

► Our study underlines the importance of US evaluation in addition to clinical evaluation of Achilles enthesitis in PsA. The data from our study, along with that from previous studies, lead to the question if inflammatory findings ought to be more weighted than structural damage in the further development of US enthesitis scores, which currently include both inflammatory signs and structural damage.

METHODS

Patients
In total, there were 581 patients with PsA registered in the outpatient clinic of the Hospital of Southern Norway Trust, Norway, during the study period from January 2013 to May 2014, of whom 471 fulfilled the ClASsi-fication for Psoriatic ARthritis criteria. Of these 471 patients, 141 were included in the study in a random manner by the study nurses at consecutive clinic visits. All the included patients had peripheral inflammatory involvement clinically. A comparison of the study participants and non-participants is previously reported (online supplementary table 1). Clinical examination of the Achilles tendons was performed by two specially trained nurses, unaware of the US findings. The presence of clinical enthesitis was defined as tenderness on firm palpation at the insertion of the Achilles tendon. Body mass index (BMI, kg/m²), medication, smoking status, regular physical exercise (cannot exercise due to disability or handicap/do not exercise regularly/exercise one to two times per month/one to two times per week/three or more times per week), C reactive protein (CRP, mg/L) and erythrocyte sedimentation rate (ESR, mm/h) were assessed.

US protocol
US evaluation of the Achilles entheses was performed by a rheumatologist experienced in US (APD) on the day of clinical examination. The patients were prone positioned with ankles in passive plantar flexion. The US studies were performed using two US devices (Siemens Acuson S2000 or GE logic E) both with a multifrequency linear transducer (6–18 MHz). The complete US protocol is previously described, including a head-to-head comparison of the two US devices showing very good agreement of kappa with linear weighting for grey scale (0.88, 95% CI 0.66 to 1.0) and power Doppler (PD; 1.00, 95% CI 1.0 to 1.0) enthesitis. Resolution of the images was improved by using the highest B-mode frequency of the probe still permitting favourable resolution in the depth. Imaging parameters were adjusted to optimise the contrast between examined structures. PD frequency of 9 (10) MHz was used with a pulse repetition frequency of 391 (400) Hz. PD gain was optimised by increasing gain until artefacts appeared, then by reducing gain until artefacts disappeared. The following assessments were made both longitudinally and transversely on the Achilles entheses: (1) inflammatory activity defined as the presence of hypoechogenicity, tendon thickening and/or PD signal (approximately <2 mm from the bony cortex) and (2) structural damage defined as the presence of calcifications, enthesophytes and/or erosions at tendon insertion (cortical breakage with a step down contour defect seen in two perpendicular planes at the insertion of the entheses to the bone) in accordance with current guidelines. US sum scores of inflammatory activity (0–3) and structural damage (0–3) of the Achilles were assessed.

Statistical analyses
Statistical analyses were performed using IBM SPSS Statistics (V.21.0.0.2). Demographic variables and US scores were assessed by descriptive statistics. Proportions were analysed by X² test or Fisher’s exact test as appropriate. Correlations were assessed by Spearman’s rank correlation test (non-normal distribution of data). Univariate and multivariate logistic regression analyses were performed to explore the associations between clinical characteristics (age, sex, disease duration, BMI, smoking, current use of steroids and biological disease-modifying antirheumatic drugs (bDMARDs), CRP, ESR, regular physical exercise (one to two times per month or more; yes/no) and the presence of inflammatory or structural damage on US. A univariate p-value of 0.25 was used for variable selection and a p-value of

**RESULTS**

Patients’ demographic characteristics and medications are summarised in table 1.

Examples of inflammatory and structural findings of Achilles enthesitis are displayed in figure 1. US findings of inflammatory activity and structural damage of the Achilles are summarised in table 2.

The US results were similar for patients with and without palpatory tenderness of the Achilles. A weak correlation was found between inflammatory activity on US and CRP ($r=0.13$, $p=0.03$) but not ESR ($r=0.002$, $p=0.98$). Subclinical inflammation was found in 31 (11%) of the Achilles insertions. Structural damage was found in 48 (54.5%) of the tender Achilles. No significant difference in percentages of patients with Achilles inflammatory activity or structural damage was found when comparing patients with DAS28ESR <2.6 and ≥2.6 or patients currently treated or not with bDMARDs, conventional synthetic DMARDs and steroids, except for a higher percentage of patients with structural damage among the bDMARD treated patients (62.6% vs 47.6%, $p=0.02$). Mean (SD) BMI was similar between patients with versus without US inflammatory activity ($p=0.64$) but significantly higher in patients with versus without US structural damage (28.9 kg/m$^2$ (4.4) vs 27.7 kg/m$^2$ (4.2), $p=0.02$). As secondary analyses, we explored the clinically positive but US negative Achilles (n=33), with findings of one patient each with subtalar arthritis, talocrural arthritis, talonavicular arthritis and medial tenosynovitis of the ankle as well as two patients with flexor hallucis tenosynovitis. Corresponding pathologies were similar for patients without palpatory tenderness at the Achilles.

**Logistic regression**

By means of univariate and multivariate logistic regression analyses, age, regular physical exercise, BMI and current use of bDMARDs were associated with structural damage on US (table 3). The findings were valid also when adjusted for gender and disease duration. Disease duration (OR 0.95, 95% CI 0.90 to 1.00, $p=0.05$) was the only variable associated with inflammatory activity on US in univariate analyses but was no longer significant when adjusted for age and gender.

**DISCUSSION**

Achilles enthesitis defined by US was not significantly associated with clinical enthesitis in this population of patients with PsA. Our findings underline the value of US evaluation in addition to clinical evaluation of entheses in PsA. US may give detailed information of both inflammatory and structural damage of entheses and thus could facilitate optimal treatment monitoring. Interestingly, the percentage of patients with acute inflammation and/or structural damage was similar for the groups with and without palpatory tenderness. This suggests that there may be limited value of clinical examination compared with US evaluation. In fact, US of the Achilles has previously been proposed in the diagnosis of early psoriatic arthropathy, as a sensitive method for early diagnosis.

Structural damage of the Achilles may be related not
to traditional findings of enthesitis, such as traumatic injuries, degeneration and even metabolic disorders.2 We found structural damage of the Achilles associated with age and BMI, in accordance with previous observations.13 14 More interestingly, we also found structural damage associated with current use of bDMARDs—which may be related to a history of higher disease activity in these patients—as well as with regular physical exercise. The association between structural damage and age, BMI and regular physical activity may relate to increased mechanical stress over time. This leads to the question as to what extent structural damage of the Achilles may be seen in healthy subjects. In patients with psoriasis, subclinical enthesitis has been reported to be a frequent finding.14–16 Enthesophytes of the Achilles were, in a previous study, found in a third of healthy controls compared with 90% of patients with psoriasis.14 In the same study, Achilles tendon thickening was reported in only 1 of 30 healthy controls. Importantly, structural changes of the Achilles are also known to be a rather frequent finding in athletes and after entheses overuse.17 18

The data from our study, along with that from previous studies, lead to the question if inflammatory findings ought to be more weighted than structural damage in the further development of US enthesitis scores, which currently include both inflammatory signs and structural damage.4 5 19–21

Limitations of the study include the cross-sectional, single-blinded design. For future studies, a longitudinal double-blinded design would allow the assessment of predictors of Achilles enthesis and further evaluation of the long-term outcome of acute inflammation as regards structural damage. Furthermore, eventual walking before the US assessment—which is shown to increase US enthesis scores—was not recorded.22 A further limitation is the rather rare finding of inflammatory activity, particularly PD signals. In rheumatoid arthritis, the correlation between clinical and US findings of arthritis is found to be stronger in cohorts with high compared with low disease activity.23 However, with wider therapeutic options and a great focus on treating to target, many patients do achieve low disease activity. Indeed, a strength of the study is the evaluation of a large group of outpatients with PsA in a real-life setting, providing validity to the results. Further, this is the first study to explore the association between structural findings at the Achilles and physical exercise in PsA.

In conclusion, we report the lack of association between clinical and US signs of Achilles enthesis in PsA. Age, BMI, regular physical exercise and current use of bDMARDs were associated with structural damage on US.
